NumPy arrays

Types

- So far we've used built-in python types of lists, dictionary, and sets
- NumPy provides a type called `ndarray` (n-dimensional array)

Benefits of `ndarray`

- `ndarrays` are fast and space efficiency multidimensional arrays
- They provide vectorized arithmetic operations and broadcasting capabilities
- The numpy library provides many useful mathematical functions, especially matrix operations

Limitations of `ndarray`

- NumPy does not provide high-level data analysis functionality
- But having an understanding of NumPy arrays and array-oriented computing will help

Create an ndarray

- Create an `ndarray` like so:

```
>>> import numpy as np
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr
array([[ 0. ,  1.5,  2. ],
       [-1. ,  3. ,  5. ]])
>>> type(arr)
numpy.ndarray
```

Create an ndarray

- Create an `ndarray` like so:

```
>>> import numpy as np
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr
array([[ 0. ,  1.5,  2. ],
       [-1. ,  3. ,  5. ]])
>>> type(arr)
numpy.ndarray
```

- Conveniently get its dimensions using the `shape` attribute:

```
>>> arr.shape
(2, 3)
```

Arithmetic with ndarray

- Can multiply by a number to scale:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr * 3
array([[  0.,   3.,   4.],
       [ -2.,   6.,  10.]])
```

Arithmetic with ndarray

- Can multiply by a number to scale:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr * 3
array([[  0.,   3.,   4.],
       [ -2.,   6.,  10.]])
```

- Can add two ndarrays:

```
>>> arr + arr
array([[  0.,   3.,   4.],
       [ -2.,   6.,  10.]])
```

Arithmetic with ndarray

- Can multiply by a number to scale:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr * 3
array([[  0.,   3.,   4.],
       [ -2.,   6.,  10.]])
```

- Can add two ndarrays:

```
>>> arr + arr
array([[  0.,   3.,   4.],
       [ -2.,   6.,  10.]])
```

- Multiplication is element-wise:

```
>>> arr * arr
array([[  0.  ,   2.25,   4.  ],
       [  1.  ,   9.  ,  25.  ]])
```

Indexing

On the surface, you can index an `ndarray` like a `list`:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr[1]
array([-1.,  3.,  5.])
>>> arr[1][1:3]
array([ 3.,  5.])
```

Assignment

Unlike with a regular list, you can assign a value to a slice of an `ndarray`:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr[1][:] = 0
>>> arr
array([[ 0. ,  1.5,  2. ],
       [ 0. ,  0. ,  0. ]])
```

Mathematical functions

NumPy `ndarrays` have many builtin mathematical functions:

```
>>> arr = np.array([[0, 1.5, 2.0],
                    [-1.0, 3.0, 5.0]])
>>> arr.sum()
3.5
>>> arr.min()
0.0
>>> arr.max()
2.0
>>> arr.std()
0.83748963509340746
```

Mathematical functions per axis

In addition to calculating these values across the entire `ndarray` you can calculate per axis:

```
>>> ar = np.array([[0, 1.5, 2.0],
                   [-1.0, 3.0, 5.0]])
>>> arr.sum(axis=0)
array([ 0. ,  1.5,  2. ])
>>> arr.sum(axis=1)
array([ 3.5,  0. ])
```

Pandas

Overview

- Pandas is an important module for data analysis in python
- Pandas builds on numpy to provide data structures with:
  - Mixed types
  - Column and row names
  - Time series functionality
  - Lots of input and output formats (CSV, MS Excel, etc.)
  - Easy plotting with `matplotlib`

Data structures

There are two main data structures (types) in pandas: `Series` and `DataFrame`.

Pandas Series

Overview

A Series is a one-dimensional object (like a list or a 1d ndarray).
Additionally, a Series stores an array of data labels, called its index.

Series creation

- Create a series from a list:

```
>>> import pandas as pd
>>> s = pd.Series([3,10,5,4,-1])
>>> s
0     3
1    10
2     5
3     4
4    -1
dtype: int64
```

- Notes:
  - Python represents the Series with the index on the left and the values on the right.
  - Since we didn't specify an index, the default is like a list: 0 through N-1 where N is the length of the data.
  - Pandas automatically assigned a datatype (`dtype`) of integer (`int64`) to this Series

Specifying an index

To specify a label for each point in the Series, called an index:

```
>>> s = pd.Series(
        [3,10,5,4],
        index=['Dorothy', 'Alice', 'Chris', 'Bob'])
>>> s
Dorothy     3
Alice      10
Chris       5
Bob         4
dtype: int64
```

Using an index

Now we can use the index to select from the series:

```
>>> s['Chris']
5
>>> s['Bob'] = -10
>>> s[['Alice', 'Bob']]
Alice    10
Bob     -10
dtype: int64
```

Selecting multiple values returns a (sub-)`Series`.

Operations

- ```
  >>> s*2
  Dorothy     6
  Alice      20
  Chris      10
  Bob       -20
  dtype: int64
  ```

- ```
  >>> s >= 10
  Dorothy    False
  Alice       True
  Chris      False
  Bob        False
  dtype: bool
  ```

- ```
  >>> s.sum()
  22
  ```
  ```

Boolean filtering

You can subset a Series with series of the same index that has boolean values:

```
>>> s[s >= 10]
Alice      10
dtype: int64
```

`in` keyword

The `in` operator checks the index of a Series:

```
>>> 'Alice' in s
True
>>> 'Eric' in s
False
```

Alternative constructor

You can also think of a Series like a dictionary where the keys are the index. Unlike a dictionary, a Series is ordered. You can construct a series from a dictionary:

```
>>> s_data = {'Ohio': 35000, 'Texas': 71000,
              'Oregon': 16000, 'Utah': 5000}
>>> s2 = pd.Series(s_data)
>>> s2
Ohio      35000
Oregon    16000
Texas     71000
Utah       5000
dtype: int64
```

Missing values

You can also specify an index when passing a dictionary:

```
>>> s2 = pd.Series(s_data,
                   index=['California', 'Texas', 'Utah'])
>>> s2
California        NaN
Texas         71000.0
Utah           5000.0
dtype: float64
```

Missing entries have the special value `NaN` (not-a-number).

Working with missing values

- Use `dropna()` to get a sub-series without the missing values

```
>>> s2.dropna()
Texas    71000.0
Utah      5000.0
dtype: float64
```

Working with missing values

- Use `dropna()` to get a sub-series without the missing values

```
>>> s2.dropna()
Texas    71000.0
Utah      5000.0
dtype: float64
```

- Use `.isnull()` and `.notnull()` to get a boolean series indicating whether the value was null or not:

```
>>> s2.isnull()
California     True
Texas         False
Utah          False
dtype: bool
```

Working with missing values

- Use `dropna()` to get a sub-series without the missing values

```
>>> s2.dropna()
Texas    71000.0
Utah      5000.0
dtype: float64
```

- Use `.isnull()` and `.notnull()` to get a boolean series indicating whether the value was null or not:

```
>>> s2.isnull()
California     True
Texas         False
Utah          False
dtype: bool
```

- You can use this series for indexing or in its own right:

```
>>> s2.notnull().sum()
2
```

Series alignment

If you perform an operation between two Series with different indexes, the result will be indexed by their union:

```
>>> s + s2
Alice         NaN
Bob           NaN
California    NaN
Chris         NaN
Dorothy       NaN
Texas         NaN
Utah          NaN
dtype: float64
```

Pandas DataFrame

Overview

- A `DataFrame` is like a table or a spreadsheet
- It has an ordered list of columns
- The columns can have mixed types (e.g. numeric, boolean, string, etc.)

DataFrame anatomy

- Each column is a pandas `Series`
- The columns all share the same index, called the row index of the data frame
- The names of the columns form a second index, called the column index

Constructing a DataFrame

The most common way to construct a DataFrame in python is using a dictionary where the keys are column names and the values are equal length lists of data:

```
>>> data = {
        'state': ['Ohio', 'Ohio', 'Ohio',
                  'Nevada', 'Nevada'],
        'year': [2000, 2001, 2002, 2001, 2002],
        'pop': [1.5, 1.7, 3.6, 2.4, 2.9]}
>>> df = pd.DataFrame(data)
>>> df
   pop   state  year
0  1.5    Ohio  2000
1  1.7    Ohio  2001
2  3.6    Ohio  2002
3  2.4  Nevada  2001
4  2.9  Nevada  2002
```

Row-index

You can also pass a row index to the DataFrame constructor:

```
>>> df = pd.DataFrame(data,
            index=['one', 'two', 'three',
                   'four', 'five'])
>>> df
       pop    state  year
one    1.5     Ohio  2000
two    1.7     Ohio  2001
three  3.6     Ohio  2002
four   2.4   Nevada  2001
five   2.9   Nevada  2002
```

Retrieving a column

- A column can be accessed in two equivalent ways
- They return a series that is *named* and index is the same as the DataFrame.

```
>>> df.state
one         Ohio
two         Ohio
three       Ohio
four      Nevada
five      Nevada
Name: state, dtype: object
```

```
>>> df['pop']
one       2000
two       2001
three     2002
four      2001
five      2002
Name: year, dtype: int64
```

Retrieving multiple columns

Retrieve multiple columns using the dict notation and passing a list of column names:

```
>>> df[['year', 'state']]
       year   state
one    2000    Ohio
two    2001    Ohio
three  2002    Ohio
four   2001  Nevada
five   2002  Nevada
```

Retrieving rows

Retrieve rows using `.loc[]`:

```
>>> df.loc['three']
pop       3.6
state    Ohio
year     2002
Name: three, dtype: object
```

```
>>> df.loc[['two','four']]
      pop   state  year
two   1.7    Ohio  2001
four  2.4  Nevada  2001
```

Boolean Series indexing

As with Series, we can subset rows using booleans:

```
>>> df[df['pop'] > 2.5]
       pop   state  year
three  3.6    Ohio  2000
five   2.9  Nevada  2000
```

Boolean Series logic

You can perform logic on boolean series to create more complicated queries. Instead of using the usual python `and`, `or`, and `not` operators, we must use special symbols `&`, `|` and `~`:

```
>>> (df.state == 'Ohio') & (df.year > 2000)
one      False
two       True
three     True
four     False
five     False
dtype: bool
```

```
>>> ~(df.state == 'Nevada')
one       True
two       True
three     True
four     False
five     False
Name: state, dtype: bool
```

Boolean Series logic indexing

```
>>> df[(df.state == 'Ohio') & (df.year > 2000)]
       pop state  year
two    1.7  Ohio  2001
three  3.6  Ohio  2002
```

Create and assigning columns

- You can initialize a new column with a constant value:

```
>>> df['debt'] = 1.5
>>> df
       pop   state  year  debt
one    1.5    Ohio  2000   1.5
two    1.7    Ohio  2001   1.5
three  3.6    Ohio  2002   1.5
four   2.4  Nevada  2001   1.5
five   2.9  Nevada  2002   1.5
```

Create and assigning columns

- You can initialize a new column with a constant value:

```
>>> df['debt'] = 1.5
>>> df
       pop   state  year  debt
one    1.5    Ohio  2000   1.5
two    1.7    Ohio  2001   1.5
three  3.6    Ohio  2002   1.5
four   2.4  Nevada  2001   1.5
five   2.9  Nevada  2002   1.5
```

- Or you can use a list. If the column exists its values are updated:

```
>>> df['debt'] = [1.0, 3.0, 2.0, 4.0, 2.5]
```

More column creation

You can also create a column using existing columns:

```
>>> df['debt_per_pop'] = df.debt / df['pop']
>>> df
       pop    state  year  debt  debt_per_pop
one    1.5     Ohio  2000   1.5      1.000000
two    1.7     Ohio  2001   1.5      0.882353
three  3.6     Ohio  2002   1.5      0.416667
four   2.4   Nevada  2001   1.5      0.625000
five   2.9   Nevada  2002   1.5      0.517241
```
